

# Storm Surges

January 21, 2014

## Abstract

Abstract to be completed

## 1 Introduction

[1]

## 2 Model Evaluation

### 2.1 River forcing

River input provides a significant volume of freshwater to the Salish Sea and can influence stratification, circulation and primary productivity. However, most rivers in the domain are not gauged so parameterisations were required to represent river flow. [2] provides a method for estimating freshwater runoff in the Salish Sea region based on precipitation. Exact data were acquired from [2], including the runoff volumes for each watershed for each year from 1970 to 2012, as well as monthly averages.

Freshwater runoff from each watershed was divided between the rivers in that watershed, based on estimations of the area that each river drained in its catchment. The area drained by each river was estimated from Toporama maps by the Atlas of Canada and watershed maps available on the Washington State government website. The watersheds included in our model were Fraser (which represents approximately 44% of the freshwater input into the region), Skagit (12%), East Vancouver Island (North and South) (12%), Howe (7%), Bute (7%), Puget (6%), Juan de Fuca (5%), Jervis (4%) and Toba (3%).

The monthly flow from each river was input as a point source in the 3 grid points closest to the surface at the model point closest to the mouth of each river. Incoming water was assumed to be fresh, with a temperature of ?? degrees C. A total of 150 rivers were parametrised by this method.
